Chapter 1

Complex traits in multiparental populations

Chapter 2

Methods development

2.1 Introduction

Complex trait studies in multiparental populations present new challenges in statistical methods and data analysis. Among these is the development of strategies for multivariate trait analysis. The joint analysis of two or more traits allows one to address additional questions, such as whether two traits share a single pleiotropic locus.

Previous research addressed the question of pleiotropy vs. separate QTL in two-parent crosses. Jiang and Zeng (1995) developed a likelihood ratio test for pleiotropy vs. separate QTL for a pair of traits. Their approach assumed that each trait was affected by a single QTL. Under the null hypothesis, the two traits were affected by a common QTL, and under the alternative hypothesis the two traits were affected by distinct QTL. Knott and Haley (2000) used linear regression to develop a fast approximation to the test of Jiang and Zeng (1995), while Tian et al. (2016) used the methods from Knott and Haley (2000) to dissect QTL hotspots in a F₂ population.

Multiparental populations, such as the Diversity Outbred (DO) mouse population (Churchill, Gatti, et al., 2012), enable high-precision mapping of complex traits (Koning and McIntyre, 2014). The DO mouse population began with progenitors of the Collaborative Cross (CC) mice (Churchill, Airey, et al., 2004) Each DO mouse is a highly heterozygous genetic mosaic of alleles from the eight CC founder lines. Random matings among non-siblings have maintained the DO population for more than 23 generations (Chesler et al., 2016).

Several limitations of previous pleiotropy vs. separate QTL tests prevent their direct application in

multiparental populations. First, multiparental populations can have complex patterns of relatedness among subjects, and failure to account for these patterns of relatedness may lead to spurious results (J. Yang et al., 2014). Second, previous tests allowed for only two founder lines (Jiang and Zeng, 1995). Finally, Jiang and Zeng (1995) assumed that the null distribution of the test statistic follows a chi-square distribution.

We developed a pleiotropy vs. separate QTL test for two traits in multiparental populations. Our test builds on research that Jiang and Zeng (1995), Knott and Haley (2000), Tian et al. (2016), and Zhou and Stephens (2014) initiated. Our innovations include the accommodation of k founder alleles per locus (compared to the traditional two founder alleles per locus) and the incorporation of multivariate polygenic random effects to account for relatedness. Furthermore, we implemented a parametric bootstrap to calibrate test statistic values (Efron, 1979; Tian et al., 2016).

Below, we describe our likelihood ratio test for pleiotropy vs. separate QTL. In simulation studies, we find that it is slightly conservative, and that it has power to detect two separate loci when the univariate LOD peaks are strong. We further illustrate our approach with an application to data on a pair of behavior traits in a population of 261 DO mice (Logan et al., 2013; Recla et al., 2014). We find modest evidence for distinct QTL in a 2.5-cM region on mouse Chromosome 8.

2.2 Methods

Our strategy involves first identifying two traits that map to a common genomic region. We then perform a two-dimensional, two-QTL scan over the genomic region, with each trait affected by one QTL of varying position. We identify the QTL position that maximizes the likelihood under pleiotropy (that is, along the diagonal where the two QTL are at a common location), and the ordered pair of positions that maximizes the likelihood under the model where the two QTL are allowed to be distinct. The logarithm of the ratio of the two likelihoods is our test statistic. We calibrate this test statistic with a parametric bootstrap.

2.2.1 Data structures

The data consist of three objects. The first is an n by k by m array of allele probabilities for n subjects with k alleles and m marker positions on a single chromosome [derived from the observed SNP genotype data by a hidden Markov model; see K. W. Broman et al. (2019)]. The second object is an n by 2 matrix of phenotype values. Each column is a phenotype and each row is a subject. The third object is an n by c matrix of covariates, where each row is a subject and each column is a covariate.

One additional object is the genotype-derived kinship matrix, which is used in the linear mixed model to account for population structure. We are focusing on a defined genomic interval, and we prefer to use a kinship matrix derived by the "leave one chromosome out" (LOCO) method (J. Yang et al., 2014), in which the kinship matrix is derived from the genotypes for all chromosomes except the chromosome under test.

2.2.2 Statistical Models

Focusing on a pair of traits and a particular genomic region of interest, the next step is a two-dimensional, two-QTL scan (Jiang and Zeng, 1995). We consider two QTL with each affecting a different trait, and consider all possible pairs of locations for the two QTL. For each pair of positions, we fit the multivariate linear mixed effects model defined in Equation 2.1. Note that we have assumed an additive genetic model throughout our analyses, but extensions to design matrices that include dominance are straightforward.

$$vec(Y) = Xvec(B) + vec(G) + vec(E)$$
(2.1)

where Y is the n by 2 matrix of phenotypes values; X is a 2n by 2(k+c) matrix that contains the k allele probabilities for the two QTL positions and the c covariates in diagonal blocks; B is a (k+c) by 2 matrix of allele effects and covariate effects; G is a n by 2 matrix of random effects; and E is a n by 2 matrix of random errors. n is the number of mice. The 'vec' operator stacks columns from a matrix into a single vector. For example, a 2 by 2 matrix inputted to 'vec' results in a vector with length 4. Its first two entries are the matrix's first column, while the third and fourth entries are the matrix's second column.

We also impose distributional assumptions on G and E:

$$G \sim MN_{nx2}(0, K, V_q) \tag{2.2}$$

and

$$E \sim MN_{nx2}(0, I, V_e) \tag{2.3}$$

where $MN_{nx2}(0, V_r, V_c)$ denotes the matrix-variate (n by 2) normal distribution with mean being the n by 2 matrix with all zero entries and row covariance V_r and column covariance V_c . We assume that G and E are independent.

2.2.3 Parameter inference and log likelihood calculation

Inference for parameters in multivariate linear mixed effects models is notoriously difficult and can be computationally intense (K. Meyer, 1989; K. Meyer, 1991). Thus, we estimate V_g and V_e under the null hypothesis of no QTL, and then take them as fixed and known in our two-dimensional, two-QTL genome scan. We use restricted maximum likelihood methods to fit the model:

$$vec(Y) = X_0 vec(B) + vec(G) + vec(E)$$
(2.4)

where X_0 is a 2n by 2(c+1) matrix whose first column of each diagonal block in X_0 has all entries equal to one (for an intercept); the remaining columns are the covariates.

We draw on our R implementation (Boehm, 2018a) of the GEMMA algorithm for fitting a multivariate linear mixed effects model with expectation-maximization (Zhou and Stephens, 2014). We use restricted maximum likelihood fits for the variance components V_g and V_e in subsequent calculations of the generalized least squares solution \hat{B} .

$$\hat{B} = (X^T \hat{\Sigma}^{-1} X)^{-1} X^T \hat{\Sigma}^{-1} vec(Y)$$

$$(2.5)$$

where

$$\hat{\Sigma} = \hat{V}_q \otimes K + \hat{V}_e \otimes I_n \tag{2.6}$$

where \otimes denotes the Kronecker product, K is the kinship matrix, and I_n is a n by n identity matrix. We then calculate the log likelihood for a normal distribution with mean $Xvec(\hat{B})$ and covariance $\hat{\Sigma}$ that depends on our estimates of V_g and V_e (Equation 2.6).

2.2.4 Pleiotropy vs. separate QTL hypothesis testing framework

Our test applies to two traits considered simultaneously. Below, λ_1 and λ_2 denote putative locus positions for traits one and two. We quantitatively state the competing hypotheses for our test as:

$$H_0: \lambda_1 = \lambda_2$$

$$H_A: \lambda_1 \neq \lambda_2 \tag{2.7}$$

Our likelihood ratio test statistic is:

$$LOD = \log_{10} \left[\frac{\max_{\lambda_1, \lambda_2} L(B, \Sigma, \lambda_1, \lambda_2)}{\max_{\lambda} L(B, \Sigma, \lambda, \lambda)} \right]$$
(2.8)

where L is the likelihood for fixed QTL positions, maximized over all other parameters.

2.2.5 Visualizing profile LOD traces

The output of the above analysis is a two-dimensional \log_{10} likelihood surface. To visualize these results, we followed an innovation of Zeng et al. (2000) and Tian et al. (2016), and plot three traces: the results along the diagonal (corresponding to the null hypothesis of pleiotropy), and then the profiles derived by fixing one QTL's position and maximizing over the other QTL's position.

We define the LOD score for our test:

$$LOD(\lambda_1, \lambda_2) = ll_{10}(\lambda_1, \lambda_2) - \max ll_{10}(\lambda, \lambda)$$
(2.9)

where ll_{10} denotes log_{10} likelihood.

We follow Zeng et al. (2000) and Tian et al. (2016) in defining profile LOD by the equation

profile
$$LOD_1(\lambda_1) = \max_{\lambda_2} LOD(\lambda_1, \lambda_2)$$
 (2.10)

We define profile $LOD_2(\lambda_2)$ analogously. The maximum value for the profile LOD_1 profile LOD_2 traces are the same and are non-negative, and give the overall LOD test statistic.

We construct the pleiotropy trace by calculating the log-likelihoods for the pleiotropic models at every position.

$$LOD_{p}(\lambda) = ll_{10}(\lambda, \lambda) - \max ll_{10}(\lambda, \lambda)$$
(2.11)

By definition, the maximum value for this pleiotropy trace is zero.

2.2.6 Bootstrap for test statistic calibration

We use a parametric bootstrap to calibrate our test statistic (Efron, 1979). While Jiang and Zeng (1995) used quantiles of a chi-squared distribution to determine p-values, this does not account for the two-dimensional

search over QTL positions. We follow the approach of Tian et al. (2016), and identify the maximum likelihood estimate of the QTL position under the null hypothesis of pleiotropy. We then use the inferred model parameters under that model and with the QTL at that position to simulate bootstrap data sets according to the model in equations 2.1–2.3. For each of b bootstrap data sets, we perform a two-dimensional QTL scan (over the genomic region of interest) and derive the test statistic value. We treat these b test statistics as the empirical null distribution, and calculate a p-value as the proportion of the b bootstrap test statistics that equal or exceed the observed one, with the original data, $p = \#\{i : \text{LOD}_i^* \geq \text{LOD}\}/b$ where LOD_i^* denotes the LOD score for the ith bootstrap replicate and LOD is the observed test statistic.

2.2.7 Data & Software Availability

Our methods have been implemented in an R package, qt12pleio, available at GitHub:

https://github.com/fboehm/qtl2pleio

Custom R code for our analyses and simulations are at GitHub:

https://github.com/fboehm/qt2pleio-manuscript

The data from Recla et al. (2014) and Logan et al. (2013) are available at the Mouse Phenome Database:

https://phenome.jax.org/projects/Chesler4 and https://phenome.jax.org/projects/Recla1.

They are also available in R/qtl2 format at https://github.com/rqtl/qtl2data.

2.3 Simulation studies

We performed two types of simulation studies, one for type I error rate assessment and one to characterize the power to detect separate QTL. To simulate traits, we specified X, B, V_g , K, and V_e matrices (Equations 2.1–2.3). For both we used the allele probabilities from a single genomic region derived empirically from data for a set of 479 Diversity Outbred mice from Keller et al. (2018).

2.3.1 Type I error rate analysis

To quantify type I error rate (i.e., false positive rate), we simulated 400 pairs of traits for each of eight sets of parameter inputs (Table 2.1). We used a 2^3 factorial experimental design with three factors: allele effects difference, allele effects partitioning, and genetic correlation, i.e., the off-diagonal entry in the 2 by 2 matrix V_g .

Table 2.1: Type I error rates for all runs in our 2^3 experimental design. We set (marginal) genetic variances (i.e., diagonal elements of V_g) to 1 in all runs. V_e was set to the 2 by 2 identity matrix in all runs. We used allele probabilities at a single genetic marker to simulate traits for all eight sets of parameter inputs. In the column "Allele effects partitioning", "ABCD:EFGH" means that lines A-D carry one QTL allele while lines E-H carry the other allele. "F:ABCDEGH" means the QTL has a private allele in strain F.

Run	Δ (Allele effects)	Allele effects partitioning	Genetic correlation	Type I error rate
1	6	ABCD:EFGH	0	0.032
2	6	ABCD:EFGH	0.6	0.035
3	6	F:ABCDEGH	0	0.040
4	6	F:ABCDEGH	0.6	0.045
5	12	ABCD:EFGH	0	0.038
6	12	ABCD:EFGH	0.6	0.042
7	12	F:ABCDEGH	0	0.025
8	12	F:ABCDEGH	0.6	0.025

We chose two strong allele effects difference values, 6 and 12. These ensured that the univariate phenotypes mapped with high LOD scores to the region of interest. For the allele partitioning factor, we used either equally frequent QTL alleles, or a private allele in the CAST strain (F). For the residual genetic correlation (the off-diagonal entry in V_g), we considered the values 0 and 0.6. The marginal genetic variances (*i.e.*, the diagonal entries in V_g) for each trait were always set to one.

We performed 400 simulation replicates per set of parameter inputs, and each used b = 400 bootstrap samples. For each bootstrap sample, we calculated the test statistic (Equation 2.8). We then compared the test statistic from the simulated trait against the empirical distribution of its 400 bootstrap test statistics. When the simulated trait's test statistic exceeded the 0.95 quantile of the empirical distribution of bootstrap test statistics, we rejected the null hypothesis. We observed that the test is slightly conservative over our range of parameter selections (Table 2.1), with estimated type I error rates < 0.05.

2.3.2 Power analysis

We also investigated the power to detect the presence of two distinct QTL. We used a $2 \times 2 \times 5$ experimental design, where our three factors were allele effects difference, allele effects partitioning, and inter-locus distance. The two levels of allele effects difference were 1 and 2. The two levels of allele effects partitioning were as in the type I error rate studies, ABCD:EFGH and F:ABCDEGH (Table S1). The five levels of interlocus distance were 0, 0.5, 1, 2, and 3 cM. V_g and V_e were both set to the 2 by 2 identity matrix in all power study simulations.

We simulated 400 pairs of traits per set of parameter inputs. For each simulation replicate, we calculated

Figure 2.1: Pleiotropy vs. separate QTL power curves for each of four sets of parameter settings. Factors that differ among the four curves are allele effects difference and allele partitioning. Red denotes high allele effects difference, while black is the low allele effects difference. Solid line denotes the even allele partitioning (ABCD:EFGH), while dashed line denotes the uneven allele partitioning (F:ABCDEGH).

the likelihood ratio test statistic. We then applied our parametric bootstrap to calibrate the test statistics. For each simulation replicate, we used b = 400 bootstrap samples. Because the bootstrap test statistics within a single set of parameter inputs followed approximately the same distribution, we pooled the 400*400 = 160,000 bootstrap samples per set of parameter inputs and compared each test statistic to the empirical distribution derived from the 160,000 bootstrap samples. However, for parameter inputs with interlocus distance equal to zero, we didn't pool the 160,000 bootstrap samples; instead, we proceeded by calculating power (*i.e.*, type I error rate, in this case), as we did in the type I error rate study above.

We present our power study results in Figure 2.1. Power increases as interlocus distance increases. The top two curves correspond to the case where the QTL effects are largest. For each value for the QTL effect, power is greater when the QTL alleles are equally frequent, and smaller when a QTL allele is private to one strain. One can have high power to detect that the two traits have distinct QTL when they are separated by > 1 cM and when the QTL have large effect.

2.4 Application

To illustrate our methods, we applied our test to data from Logan et al. (2013) and Recla et al. (2014), on 261 DO mice measured for a set of behavioral phenotypes. Recla et al. (2014) identified Hydin as the gene that underlies a QTL on Chromosome 8 at 57 cM for the "hot plate latency" phenotype (a measure of pain tolerance). The phenotype "percent time in light" in a light-dark box (a measure of anxiety) was measured on the same set of mice (Logan et al., 2013) and also shows a QTL near this location, which led us to ask whether the same locus affects both traits. The two traits show a correlation of -0.15 (Figure S1).

QTL analysis with the LOCO method, and using sex as an additive covariate, showed multiple suggestive QTL for each phenotype (Figure S2; Table S2). For our investigation of pleiotropy, we focused on the interval 53–64 cM on Chromosome 8. The univariate QTL results for this region are shown in Figure 2.2.

The estimated QTL allele effects for the two traits are quite different (Figure 2.3). With the QTL placed at 55 cM, for "percent time in light", the WSB and PWK alleles are associated with large phenotypes and NOD with low phenotypes. For "hot plate latency", on the other hand, CAST and NZO show low phenotypes and NOD and PWK are near the center.

In applying our test for pleiotropy, we performed a two-dimensional, two-QTL scan for the pair of phenotypes. With these results, we created a profile LOD plot (Figure 2.4). The profile LOD for "percent time in light" (in brown) peaks near 55 cM, as was seen in the univariate analysis. The profile LOD for "hot plate latency" (in blue) peaks near 57 cM, also similar to the univariate analysis. The pleiotropy trace (in gray) peaks near 55 cM.

The likelihood ratio test statistic for the test of pleiotropy was 1.2. Based on a parametric bootstrap with 1,000 bootstrap replicates, the estimated p-value was 0.11, indicating weak evidence for distinct QTL for the two traits.

2.5 Discussion

We developed a test of pleiotropy vs. separate QTL for multiparental populations, extending the work of Jiang and Zeng (1995) for multiple alleles and with a linear mixed model to account for population structure (Kang et al., 2010; J. Yang et al., 2014). Our simulation studies indicate that the test has power to detect presence of separate loci, especially when univariate trait associations are strong (Figure 2.1). Type I error rates indicate that our test is slightly conservative (Table 2.1).

In the application of our method to two behavioral phenotypes in a study of 261 Diversity Outbred mice

percent time in light

hot plate latency

Figure 2.2: Chromosome 8 univariate LOD scores for percent time in light and hot plate latency reveal broad, overlapping peaks between $53~\mathrm{cM}$ and $64~\mathrm{cM}$. The peak for percent time in light spans the region from approximately $53~\mathrm{cM}$ to $60~\mathrm{cM}$, with a maximum near $55~\mathrm{cM}$. The peak for hot plate latency begins near $56~\mathrm{cM}$ and ends about $64~\mathrm{cM}$.

percent time in light

hot plate latency

Figure 2.3: Chromosome 8 univariate LOD scores for percent time in light and hot plate latency reveal broad, overlapping peaks between $53~\mathrm{cM}$ and $64~\mathrm{cM}$. The peak for percent time in light spans the region from approximately $53~\mathrm{cM}$ to $60~\mathrm{cM}$, with a maximum near $55~\mathrm{cM}$. The peak for hot plate latency begins near $56~\mathrm{cM}$ and ends about $64~\mathrm{cM}$.

Figure 2.4: Profile LOD curves for the pleiotropy vs. separate QTL hypothesis test for "percent time in light" and "hot plate latency". Gray trace denotes pleiotropy LOD values. Triangles denote the univariate LOD maxima, while diamonds denote the profile LOD maxima. For "percent time in light", the brown triangle obscures the smaller brown diamond. Likelihood ratio test statistic value corresponds to the height of the blue and brown traces at their maxima.

(Recla et al., 2014; Logan et al., 2013), we obtained weak evidence (p=0.11) for the presence of two distinct QTL, with one QTL (which contained the *Hydin* gene) affecting only "hot plate latency" and a second QTL affecting "percent time in light" (Figure 2.4).

Founder allele effects plots provide further evidence for the presence of two distinct loci. As Macdonald and Long (2007) and King et al. (2012) have demonstrated in their analyses of multiparental *Drosophila* populations, a biallelic pleiotropic QTL would result in allele effects plots that have similar patterns. While we don't know that "percent time in light" and "hot plate latency" arise from biallelic QTL, the dramatic differences that we observe in allele effects patterns further support the argument for two distinct loci.

We have implemented our methods in an R package qtl2pleio, but analyses can be computationally intensive and time consuming. qtl2pleio is written mostly in R, and so we could likely obtain improved computational speed by porting parts of the calculations to a compiled language such as C or C++. To accelerate our multi-dimensional QTL scans, we have integrated C++ code into qtl2pleio, using the Rcpp package (Eddelbuettel et al., 2011).

Another computational bottleneck is the estimation of the variance components V_g and V_e . To accelerate this procedure, especially for the joint analysis of more than two traits, we will consider other strategies for variance component estimation, including that described by H. V. Meyer et al. (2018). H. V. Meyer et al. (2018), in joint analysis of dozens of traits, implement a bootstrap strategy to estimate variance components for lower-dimensional phenotypes before combining bootstrap estimates into valid covariance matrices for the full multivariate phenotype. Such an approach may ease some of the computational burdens that we encountered.

We view tests of pleiotropy as complementary to mediation tests and related methods that have become popular for inferring biomolecular causal relationships (Chick et al., 2016; Schadt et al., 2005; Baron and Kenny, 1986). A mediation test proceeds by including a putative mediator as a covariate in the regression analysis of phenotype and QTL genotype; a substantial reduction in the association between genotype and phenotype corresponds to evidence of mediation.

Mediation analyses and our pleiotropy test ask distinct, but related, questions. Mediation analysis seeks to establish causal relationships among traits, including molecular traits, or dependent biological and behavioral processes. Pleiotropy tests examine whether two traits share a single source of genetic variation, which may act in parallel or in a causal network. Pleiotropy is required for causal relations among traits. In many cases, the pleiotropy hypothesis is the only reasonable one.

Schadt et al. (2005) argued that both pleiotropy tests and causal inference methods may contribute to

gene network reconstruction. They developed a model selection strategy, based on the Akaike Information Criterion (Akaike, 1974), to determine which causal model is most compatible with the observed data. Schadt et al. (2005) extended the methods of Jiang and Zeng (1995) to consider more complicated alternative hypotheses, such as the possibility of two QTL, one of which associates with both traits, and one of which associates with only one trait. As envisioned by Schadt et al. (2005), we foresee complementary roles emerging for our pleiotropy test and mediation tests in the dissection of complex trait genetic architecture.

CAPE (Combinatorial Analysis of Pleiotropy and Epistasis) is a strategy for identifying higher-order relationships among traits and marker genotypes (Tyler, Lu, et al., 2013). Tyler, Ji, et al. (2017) used CAPE to identify epistatic gene networks in Diversity Outbred mice. Tyler, Donahue, et al. (2016) found evidence for weak epistasis in a large intercross population.

CAPE uses linear models that are distinct from those in our pleiotropy test. A CAPE starts with founder allele dosages at all markers and a collection of two or more traits (Tyler, Ji, et al., 2017). After eigendecomposition to get two or more eigentraits, univariate QTL scans are performed and founder allele effects are estimated at all markers (or a subset of all markers). Next, one identifies markers with sufficiently strong effects of at least one founder allele. Resulting (eigentrait, marker, founder allele) triples are then subjected to a second model fitting. This second round of modeling involves two (eigentrait, marker, founder allele) triples that share an eigentrait. The shared (univariate) eigentrait is modeled as a linear function of the two founder allele dosages and their interaction.

In comparing CAPE and our pleiotropy test, it's important to recognize that the two methods ask different questions. CAPE enables assessment of interactions among specific founder allele dosages at two (possibly identical) markers while examining one eigentrait at a time. Our pleiotropy test, on the other hand, jointly models two phenotypes and quantifies the evidence against the pleiotropy hypothesis by performing a two-dimensional QTL scan over a genomic region. One limitation of CAPE is its inability to account for population structure. Incorporation of a polygenic random effect into CAPE's linear models may improve its performance in multiparental populations. CAPE's methods also highlight a current limitation of our pleiotropy test. While our multivariate linear models accommodate interactions between founder allele dosages at two markers, we haven't yet incorporated this functionality into our software. It is one direction for future research.

Technological advances in mass spectrometry and RNA sequencing have enabled the acquisition of high-dimensional biomolecular phenotypes (Ozsolak and Milos, 2011; X. Han, K. Yang, and Gross, 2012). Multiparental populations in *Arabidopsis*, maize, wheat, oil palm, rice, *Drosophila*, yeast, and other organisms

enable high-precision QTL mapping (Yu et al., 2008; Tisné et al., 2017; Stanley et al., 2017; Raghavan et al., 2017; Mackay et al., 2012; Kover et al., 2009; Cubillos et al., 2013). The need to analyze high-dimensional phenotypes in multiparental populations compels the scientific community to develop tools to study genotype-phenotype relationships and complex trait architecture. Our test, and its future extensions, will contribute to these ongoing efforts.

Chapter 3

Applications

3.1 Expression trait hotspot dissection

3.1.1 Introduction

A central goal of systems genetics studies is to identify causal relationships between biomolecules. Recent work by Chick et al. (2016), which builds on research from Baron and Kenny (1986), has popularized linear regression-based methods for causal inference in genetics. This development motivates our goal of clarifying a role for our pleiotropy test. We argue that our pleiotropy test complements mediation analysis in two ways. First, our test limits the set of candidate mediators by ruling out traits that don't share a single pleiotropic QTL. Second, when regression-based mediation analysis fails to identify a mediator, our pleiotropy test still provides information on the number of QTL, which may provide clues to aid biological understanding.

We begin by discussing what it means for one trait to mediate a relationship between a DNA variant and another trait. To clarify our discussion, we refer to an example from Chick et al. (2016) (Figure 3.1). Chick et al. (2016), in studying livers of 192 Diversity Outbred mice, found evidence that *Dhtkd1* transcript levels associated with a local marker on Chromosome 2. They also found that the same marker affected DHTKD1 protein concentrations. As anticipated, mediation analysis, in which the DHTKD1 protein concentrations are regressed on founder allele dosages (at the Chromosome 2 marker) demonstrated that *Dhtkd1* transcript levels act as a mediator between DHTKD1 protein concentrations and the founder allele dosages. In fact, the extent of the reduction in association strength indicates that the primary pathway by which the genetic marker affects DHTKD1 protein concentrations is through *Dhtkd1* transcript levels.

Figure 3.1: A DNA variant in the *Dhtkd1* gene affects *Dhtkd1* transcript abundances which, in turn, affect DHTKD1 protein concentrations.

Figure 3.2: Biological information is encoded in DNA. This information is passed, via transcription, to RNA molecules. The process of translation transmits the information to proteins.

Crick (1958) articulated a pathway for transmission of biological information that is now known as the central dogma of molecular biology (Figure 3.2). In it, he argued that information encoded in DNA sequence is transmitted via transcription to RNA molecules, which, in turn, transfer the information to proteins via translation. This sequence of information transfer, from DNA to RNA to protein, provides a natural setting by which to examine mediation analysis. If a DNA variant affects protein concentrations only through its RNA transcripts, then conditioning on RNA transcript levels would greatly reduce the strength of association between DNA variant and protein concentration. In the example above, a DNA variant in the *Dhtkd1* gene affects its transcript levels, which then affect DHTKD1 protein levels (Figure 3.1).

Following Keller et al. (2018), we generalize this setting to the case where a DNA variant affects a local transcript level, which then affects a nonlocal transcript level. We term a transcript "local" to a marker when its DNA is near that marker. Typically, we use a threshold of no more than 2 Mb to restrict the number of local transcripts for a given marker. A nonlocal transcript, then, is either one that arises from a gene on another chromosome or from a distant gene on the same chromosome as the marker.

It is highly plausible that concentration variations in one transcript may affect abundances of a second transcript. For example, the first transcript may encode a transcription factor protein. In this case, the transcription factor protein may influence expression patterns of the second transcript (and perhaps other

transcripts). Alternatively, the first transcript may act directly to enhance expression of a second transcript, possibly by interacting with a complex of biomolecules in the nucleus.

To determine whether a local transcript level mediates the relationship between a nonlocal transcript level and a DNA variant, we perform a series of regression analyses, which we detail below (Equations 3.1, 3.2, 3.3, 3.4). In brief, we regress the nonlocal transcript levels on founder allele dosages at the DNA variant, with and without conditioning on the candidate mediator (the local transcript levels). If the LOD score diminishes sufficiently upon conditioning on a candidate, then we declare the candidate a mediator.

The rationale behind this strategy is as follows. If the DNA variant affects the nonlocal transcript levels solely by way of local transcript levels, then conditioning on the local transcript levels would nullify the relationship between DNA variant and the nonlocal transcript levels. At the other extreme, if the DNA variant affects nonlocal transcript levels solely through mechanisms that don't involve the local transcript levels, then conditioning on local transcript levels would not affect the association between the DNA variant and nonlocal transcript levels.

One role for our pleiotropy test is to potentially limit the set of candidate mediators that require study. For example, if local transcript levels and nonlocal transcript levels map to separate QTL, then it would be unlikely that local transcript levels affect the nonlocal transcript levels (or vice versa). On the other hand, if we believe that a single pleiotropic locus affects both local transcript levels and nonlocal transcript levels, then a mediation analysis is particularly useful in efforts to clarify the relationship between the local transcript levels and nonlocal transcript levels. In this setting, where a single pleiotropic locus affects both local transcript levels and nonlocal transcript levels, and we seek to identify the intermediate, we would perform two mediation analyses, one with local transcript levels as candidate intermediate between DNA variant and nonlocal transcript levels, and a second analysis with nonlocal transcript levels as a candidate intermediate between DNA variant and local transcript levels.

In the four linear regression models (Frame 3.1), X is a n by 8 matrix of founder allele dosages at a single marker, B is a 8 by 1 matrix of founder allele effects, E is a n by 1 matrix of random errors, b is an number, 1 is a n by 1 matrix with all entries set to 1, Y is a n by 1 matrix of phenotype values (for a single trait), and M is a n by 1 matrix of values for a putative mediator. C is a matrix of covariate effects, and W is a matrix of covariates. We denote the coefficient of the mediator by β .

We assume that the vector E is (multivariate) normally distributed with zero vector as mean and covariance matrix $\Sigma = \sigma^2 I_n$, where I_n is the n by n identity matrix.

With the above models, the log-likelihoods are easily calculated. For example, in Equation 3.1, the vector

Frame 3.1: Four regressions for a single mediation analysis

$$Y = b1 + WC + E \tag{3.1}$$

$$Y = XB + WC + E \tag{3.2}$$

$$Y = b1 + WC + M\beta + E \tag{3.3}$$

$$Y = XB + WC + M\beta + E \tag{3.4}$$

Y follows a multivariate normal distribution with mean (b1 + WC) and covariance $\Sigma = \sigma^2 I$. Thus, we can write the likelihood for Model 3.1 as:

$$L(b, C, \sigma^{2}|Y, W) = (2\pi)^{-\frac{n}{2}} \exp\left(-\frac{1}{2}(Y - b1 - WC)^{T} \Sigma^{-1}(Y - b1 - WC)\right)$$
(3.5)

We thus have the following equation (3.6 for the log-likelihood for Model 3.1:

$$\log L(b, C, \sigma^2 | Y, W) = -\frac{n}{2} \log(2\pi) - \frac{1}{2} (Y - b1 - WC)^T \Sigma^{-1} (Y - b1 - WC)$$
(3.6)

Chick et al. (2016) calculated the log₁₀ likelihoods for all four models before determining two LOD scores:

$$LOD_1 = log_{10}(Model 3.2 likelihood) - log_{10}(Model 3.1 likelihood)$$
(3.7)

$$LOD_2 = log_{10}(\text{Model 3.4 likelihood}) - log_{10}(\text{Model 3.3 likelihood})$$
(3.8)

And, finally, Chick et al. (2016) calculated the statistic:

$$LOD difference = LOD_1 - LOD_2$$
 (3.9)

LOD difference need not be positive. For example, in the setting where the putative mediator is not a true mediator, LOD_1 and LOD_2 values may lead to a negative LOD difference statistic. In our analyses in this section, we truncated these negative LOD difference values to zero.

For each mediation analysis, we consider the LOD difference proportion, which we define below (Equation 3.10).

Frame 3.2: Four assumptions for causal inference

- 1. No unmeasured confounding of the DNA variant-nonlocal transcript levels relationship
- 2. No unmeasured confounding of the local transcript levels-nonlocal transcript levels relationship
- 3. No unmeasured confounding of the DNA variant-local transcript levels relationship
- 4. No local transcript levels-nonlocal transcript levels confounder that is affected by the DNA variant

$$LOD difference proportion = \frac{(LOD_1 - LOD_2)}{LOD_1}$$
(3.10)

In other words, we consider what proportion of the association strength, on the LOD scale, is diminished by conditioning on a putative mediator. This statistic differs from the LOD difference statistic in that it scales the LOD difference by LOD_1 value. We do this in efforts to accommodate the diversity of LODs in our data. While a value of 5 for LOD difference may be important for a trait with a LOD_1 of 12, another trait with a LOD_1 of 120 that has a LOD_2 of 115, suggests that nearly all of the signal remains transmitted when conditioning on the putative mediator.

To claim that the LOD difference statistic reflects a causal relationship, four assumptions about confounding are needed (VanderWeele, 2015).

It is often difficult to recognize unmeasured confounders. In studies of Diversity Outbred mice, relatedness is a possible confounder, yet the linear models (Equations 3.1, 3.2, 3.3, 3.4) fail to account for the complex relatedness patterns among Diversity Outbred mice. Scientists have developed a suite of sensitivity analysis tools to assess possible impacts of unmeasured confounders in mediation analysis. While a discussion of sensitivity analysis is beyond the scope of this thesis, it may be useful in future studies to assess robustness of mediation analysis results in the presence of unmeasured confounders. VanderWeele (2015) discusses sensitivity analysis in detail.

Another statistical challenge in mediation analysis is assessing significance of the LOD difference statistic. Multiple research teams have proposed strategies for assessing its statistical significance. Chick et al. (2016) used individual transcript levels as sham mediators and tabulated their LOD difference statistics. They then compared the observed LOD difference statistics for putative mediators to the empirical distribution of LOD difference statistics obtained from the collection of sham mediators. Keller et al. (2018), on the other hand, in their study of pancreatic islet cell biology, declared mediators those local transcripts that diminished the LOD score of nonlocal transcripts by at least 1.5 (Keller et al., 2018). While significance threshold determination

Frame 3.3: Local gene inclusion criteria

- 1. QTL peak with LOD > 40
- 2. QTL peak position within 2 Mb of hotspot center (165.5 Mb)
- 3. Gene midpoint within 2 Mb of hotspot center (165.5 Mb)

remains an active area of research, we proceed below by examining all 147 nonlocal transcript levels that Keller et al. (2018) identified as mapping to the Chromosome 2 hotspot.

3.1.2 Methods

We examined the potential that the two methods - 1. pleiotropy vs. separate QTL testing and 2. mediation analysis - could play complementary roles in efforts to dissect gene expression trait hotspots. After describing our data below, we explain our statistical analyses involving 13 local gene expression traits and 147 nonlocal gene expression traits, all of which map to a 4-Mb hotspot on Chromosome 2.

We analyzed data from 378 Diversity Outbred mice (Keller et al., 2018). Keller et al. (2018) genotyped tail biopsies with the GigaMUGA microarray (Morgan et al., 2015). They also used RNA sequencing to measure genome-wide pancreatic islet cell gene expression for each mouse at the time of sacrifice (Keller et al., 2018). They shared these data, together with inferred founder allele probabilities, on the Data Dryad site (https://datadryad.org/resource/doi:10.5061/dryad.pj105).

We examined the Chromosome 2 pancreatic islet cell expression trait hotspot that Keller et al. (2018) identified. Keller et al. (2018) found that 147 nonlocal traits map to the 4-Mb region centered at 165.5 Mb on Chromosome 2. The 147 nonlocal traits all exceeded the genome-wide LOD significance threshold, 7.18 (Keller et al., 2018). With regression-based mediation analyses, they identified transcript levels of local gene Hnf4a as a mediator of 88 of these 147 nonlocal traits.

Because Keller et al. (2018) reported that some nonlocal traits that map to the Chromosome 2 hotspot did not demonstrate evidence of mediation by Hnf4a expression levels, we elected to study a collection of local gene expression traits, rather than Hnf4a alone. This strategy enabled us to ask whether one of twelve other local traits mediates those nonlocal hotspot traits that are not mediated by Hnf4a. Our set of local gene expression traits includes Hnf4a and 12 other local genes (Table 3.1). Our 13 local genes are the only genes that met all of the following criteria:

The 147 nonlocal traits that we studied all had LOD peak heights above 7.18 and LOD peak positions

within 2 Mb of the center of the hotspot (at 165.5 Mb).

We used both univariate and bivariate QTL scans. In the univariate scans, we identified LOD peaks for each of 160 (147 nonlocal and 13 local) expression traits that mapped to within 2 Mb of the center of the Chromosome 2 expression trait hotspot. Keller et al. (2018) provided univariate QTL mapping results, so we didn't repeat the univariate QTL scans. For a given univariate phenotype, Keller et al. (2018) fitted a linear mixed effects model (with polygenic random effect) at every marker across the genome. Keller et al. (2018) performed calculations with the qt12 R package (K. W. Broman et al., 2019).

Our analyses involved 13 local expression traits and 147 nonlocal expression traits. We described above (Frame 3.3) the criteria for choosing these expression traits.

We performed a series of two-dimensional QTL scans in which we paired each local gene's transcript levels with each nonlocal gene's transcript levels, for a total of 13 * 147 = 1,911 two-dimensional scans. Each scan examined the same set of 180 markers, which spanned the interval from 163.1 Mb to 167.8 Mb and included univariate peaks for all 13 + 147 = 160 expression traits. We performed these analyses with the R package qtl2pleio (Boehm, 2018b).

For each QTL scan, we fitted a collection of bivariate models for all 180 * 180 = 32,400 ordered pairs of markers. Throughout our analyses, we treated the founder allele dosages as known, despite the fact that they are inferred through hidden Markov model methods (Karl W Broman, 2012a; Karl W Broman, 2012b; K. W. Broman et al., 2019). For each ordered pair of markers, we fitted a multivariate linear mixed effects model with the methods of Chapter 2.

We performed linear regression-based mediation analyses for all 1,911 local-nonlocal trait pairs. We probed the extent to which each nonlocal trait's association strength diminished upon conditioning on transcript levels of a putative mediator. Each of the 13 local expression traits, considered one at a time, served as putative mediators. We thus fitted the four linear regression models that we describe above (Equations 3.1, 3.2, 3.3, 3.4).

One question that needs clarification is the choice of genetic marker for each mediation analysis. We elected to use the founder allele dosages at the marker that demonstrated the univariate LOD peak for the putative mediator. Alternative analyses, in which one uses the founder allele dosages at which the nonlocal trait has its univariate peak, are also possible.

To visualize the summary statistics for our two methods, we plotted, for each local gene, a scatterplot of LOD difference proportion values against pleiotropy test statistics.

We also examined the 1,911 pairs from the per-nonlocal gene perspective. For each of the 147 nonlocal

Table 3.1: Local gene annotations for analysis of Chromosome 2 expression trait hotspot. All positions are in units of Mb on Chromosome 2. LOD peak position and LOD peak height refer to those obtained from univariate analyses. "Start" and "end" refer to the local gene's DNA start and end positions, as annotated by Ensembl version 75.

genes, we plotted LOD difference proportion against pleiotropy test statistic values. We present below (Figure 3.6) examples that illustrate some of the observed patterns between pleiotropy test statistics and LOD difference proportion values.

3.1.3 Results

We present below our scatter plot for all 147 * 13 = 1,911 pairs of traits (Figure 3.3). Each pair contains one local expression trait and one nonlocal expression trait. Each point in the figure represents a single pair. We see that points with high values of LOD difference proportion tend to have small values of pleiotropy test statistic, and those points with high values of the pleiotropy test statistic tend to have small values of LOD difference proportion.

Some points demonstrate large values of pleiotropy test statistic (eg., > 10), yet still have sizeable LOD difference proportion statistics (Figure 3.3. One possible explanation for such points is that the univariate LOD (LOD₁) value is small, so that even a modest LOD difference gives rise to a sizeable LOD difference proportion value. A second possible explanation is that the phenotype variances for both phenotypes in the pair are large enough to skew the null distribution of the test statistic towards larger values. To distinguish between these two, we would examine the LOD difference statistics and obtain bootstrap p-values.

In Figure 3.3, we colored blue the points that involve Hnf4a; points with other local genes are red. The most striking feature of the coloring is that many blue points have small values of the pleiotropy test statistics

Figure 3.3: LOD difference proportion against pleiotropy vs. separate QTL test statistics for 1911 pairs of traits. Each point represents a single pair. Pairs that involve local expression trait Hnf4a are colored blue, while all others are colored red. Note the high prevalence of blue points in the upper left quadrant of the figure. These points, with low values of the pleiotropy vs. separate QTL test statistic and high values of LOD difference proportion, are consistent with Hnf4a transcript levels mediating the effect of Hnf4a genetic variants affecting nonlocal transcript abundances.

and very high values of LOD difference proportion.

To more thoroughly examine the relationships across the 13 local genes, we created 13 plots of LOD difference proportion against pleiotropy test statistic (Figures 3.4 and 3.5). They reveal common patterns. First, we see no points in the upper right quadrant of each plot (Figure 3.5). This tells us that those nonlocal genes with high values of pleiotropy test statistic (when paired with the specified local gene) have low values of LOD difference proportion. Similarly, those nonlocal genes with high values of LOD difference proportion tend to have small values of the pleiotropy test statistic. Finally, some trait pairs demonstrate low values of both the LOD difference proportion and pleiotropy test statistic. This observation suggests that, for a given local expression trait, the nonlocal trait is not mediated by the local expression trait yet it shares a

pleiotropic locus. Low power to resolve multiple nearby QTL may give rise to such findings.

In comparing the *Hnf4a* plot (Figure 3.4) with the other 12 plots (Figure 3.5), we see that none of the 12 plots in Figure 3.5 closely resembles Figure 3.4. *Serinc3*, *Stk4*, *Neurl2*, and *Cdh22* are closest in appearance to the plot of *Hnf4a*. However, each of *Serinc3*, *Stk4*, *Neurl2*, and *Cdh22* has very few points with LOD difference proportion above 0.5, while *Hnf4a* has many points with LOD difference proportion above 0.5.

Table 3.2: Number of nonlocal gene expression traits for which each local gene expression trait is the strongest mediator.

Scatter plots of LOD difference proportion values against pleiotropy vs. separate QTL test statistics for each of the 147 nonlocal expression traits demonstrated multiple patterns. Eighty-nine nonlocal genes' plots showed Hnf4a to have the greatest value, among the 13 putative mediators, of the LOD difference proportion statistic. In many cases, Hnf4a's LOD difference proportion statistic was at least twice that of any of the other 12 local gene expression levels.

3.1.4 Discussion

Our pairwise analyses with both mediation analyses and pleiotropy tests provide additional evidence for the importance of Hnf4a in the biology of the Chromosome 2 hotspot in pancreatic islet cells. Our analyses, and, specifically, the test of pleiotropy vs. separate QTL, may be more useful when studying nonlocal traits that map to a hotspot yet don't show strong evidence of mediation by local expression traits. In such a setting, the pleiotropy test can, at least, provide some information about the genetic architecture at the hotspot. Specifically, our pleiotropy test may inform inferences about the number of underlying QTL in a given expression trait hotspot. Additionally, our test may limit the number of expression traits that are potential

Figure 3.4: Scatter plot of LOD difference proportion against pleiotropy vs. separate QTL test statistic for 147 pairs of traits. Each pair includes Hnf4a and one of the nonlocal gene expression traits that map to the Chromosome 2 hotspot.

Figure 3.5: Scatter plots of LOD difference proportion against pleiotropy vs. separate QTL test statistic with 147 pairs of traits per panel. Each panel includes a local gene expression trait (per the label in the upper right quadrant) and one of the 147 nonlocal gene expression traits that map to the Chromosome 2 hotspot.

Figure 3.6: Scatter plots for four nonlocal expression traits. Each plot features 13 points, one for each local gene expression trait. The vertical axis denotes LOD difference proportion values, while the horizontal axis corresponds to pleiotropy test statistics. Blue points represent the pairing with local gene expression trait Hnf4a. Red points represent the other 12 local gene expression traits.

(a) Hnf4a transcript levels mediate Abcb4 transcript levels. The high LOD difference proportion and the very small pleiotropy test statistic together provide evidence that Hnf4a mediates Abcb4 transcript levels.

(c) Tmprss4 transcript levels are not mediated by any of the 13 local gene expression traits. However, several local gene expression traits arise from separate QTL, as evidenced by their large (greater than 5) values of the pleiotropy test statistic.

(b) Hnf4a transcript levels mediate Smim5 transcript levels. The high LOD difference proportion and the very small pleiotropy test statistic together provide evidence that Hnf4a mediates Smim5 transcript levels.

(d) Gm3095 transcript levels are not mediated by any of the 13 local genes. The tests of pleiotropy demonstrate evidence of separate QTL for some local expression traits when paired with Gm3095.

intermediates between a QTL and a specified nonlocal expression trait. This relies on the assumption that an intermediate expression trait and a target expression trait presumably share a QTL.

On the other hand, mediation analyses, when they provide evidence for mediation of a nonlocal trait by a local expression trait, are possibly more valuable than the test of pleiotropy vs. separate QTL, since the mediation analyses identify precisely the intermediate expression trait.

We recommend using both tests of pleiotropy vs separate QTL and mediation analyses when dissecting an expression trait QTL hotspot. In practice, mediation analyses, which involve a collection of univariate regressions at a small set of pre-specified markers, are less computationally intense than tests of pleiotropy vs. separate QTL, since the latter requires a two-dimensional QTL scan over the region of interest. This two-dimensional QTL scan often involves fitting more than ten thousand bivariate regression models. In light of the computational cost of testing pleiotropy vs separate QTL, future researchers may wish to use it as a follow-up to mediation analyses when examining expression trait hotspots.

Future research may investigate the use of polygenic random effects in the statistical models for mediation analysis. Additional methodological questions include approaches for declaring significant a mediation LOD difference proportion and consideration of other possible measures and scales of extent of mediation. Additionally, future researchers may wish to consider biological models that contain two mediators.

The social and health sciences have witnessed much methods research in mediation analysis. The field of statistical genetics has not fully adopted these strategies yet, but, given the nature of current and future data, many opportunities exist for translation of approaches from causal inference in epidemiology to systems genetics. For example, VanderWeele (2015) contains detailed discussions of many methods issues that arose in mediation analyses in epidemiology studies.

3.2 Power analyses

3.2.1 Introduction

The goal of this section is to characterize the statistical power of our pleiotropy test under a variety of conditions by studying a real data set. We examine pancreatic islet expression traits from the Keller et al. (2018) data. As in chapters 2 and 3A, we test only two traits at a time. Because we've chosen local expression traits in our analysis, we both know where each trait's true QTL location (approximately), and we anticipate that each trait has a unique QTL that is distinct from QTL for other local expression traits. This design thus provides opportunities to study statistical power for our test.

We anticipate that inter-locus distance, univariate QTL strength, and correlation of founder allele effects patterns are three factors that contribute to power for our test. Specifically, we expect that greater inter-locus distance, greater univariate LOD scores, and less similar founder allele effects patterns correspond to greater statistical power to detect two separate QTL.

We use pancreatic islet gene expression traits from a publicly available data set, which Keller et al. (2018) first collected, analyzed, and shared. We examine a collection of 80 local traits on Chromosome 19 and perform our test for pleiotropy on pairs of traits. We also examine pairwise relationships among gene expression traits to characterize the impacts of univariate LOD score, inter-locus distance, and similarity of founder allele effects patterns on pleiotropy test statistics.

3.2.2 Methods

We analyzed data from 378 Diversity Outbred mice (Keller et al., 2018). Keller et al. (2018) genotyped tail biopsies with the GigaMUGA microarray (Morgan et al., 2016). They used RNA sequencing to measure genome-wide pancreatic islet cell gene expression for each mouse at the time of sacrifice (Keller et al., 2018). They shared these data, together with inferred founder allele probabilities, on the Data Dryad site (https://datadryad.org/resource/doi:10.5061/dryad.pj105). We performed analyses with the R statistical computing environment (R Core Team, 2018) and the packages qt12 (qt12) and qt12pleio (Boehm, 2018b).

We study below 80 Chromosome 19 local expression QTL and their corresponding transcript levels. We define a local expression QTL to be an expression QTL that is on the same chromosome as the gene itself. For example, the *Asah2* gene is located on Chromosome 19 and its transcript levels have an expression QTL on Chromosome 19 (Table 3.3). Thus, we term the Chromosome 19 *Asah2* expression QTL a local expression QTL.

We choose to focus on local expression QTL, while ignoring nonlocal expression QTL, because we know, approximately, the true locations for local expression QTL. That is, a local expression QTL is near the corresponding gene position. Additionally, we expect that a given local expression QTL affects only one local expression trait. In our example above, we expect that the Asah2 expression QTL is near the Asah2 gene position and that no other local expression traits map to it.

Our design involves selection of a set of "anchor" expression traits. Gene *Asah2* is located near the center of Chromosome 19 and has a very strong local expression QTL (Table 3.3). We chose it as our first "anchor" gene expression trait. To diversify our collection of anchor genes, we chose three additional expression traits

with local expression QTL. These three are *Lipo1*, *Lipo2*, and *4933413C19Rik* (Table 3.3). Together, the four anchor genes represent a variety of strong local expression trait LOD scores (from 60 to 101) and demonstrate modest variability in their founder allele effects (Table 3.4). All four anchor genes are located near the middle of Chromosome 19 (Table 3.3).

We identified a set of 76 non-anchor local expression traits that map to the 20-Mb region centered on the peak for *Asah2*, at 32.1 Mb. Each trait among the 76 maps to Chromosome 19 with a univariate LOD score of at least 10 (Table S2).

Gene	Start	End	QTL peak position	LOD
Asah2	31.98	32.06	32.14	101.20
Lipo1	33.52	33.76	33.67	85.46
Lipo2	33.72	33.76	33.02	77.21
4933413C19Rik	28.58	28.58	28.78	60.41

Table 3.3: Annotations for four anchor genes.

For each Chromosome 19 marker, we estimated founder allele and covariate effects. We calculated:

$$\widehat{(B:C)} = \left((X:W)^T \hat{\Gamma}^{-1} (X:W) \right)^{-1} (X:W)^T \hat{\Gamma}^{-1} Y$$
(3.11)

where B:C denotes the concatenation of B and C, and X:W refers to the n by 12 matrix resulting from appending the columns of W to the X matrix. $\hat{\Gamma}$ is the covariance matrix defined by Equation 3.12.

$$\hat{\Gamma} = \hat{\sigma}_g^2 K + \hat{\sigma}_e^2 I_n \tag{3.12}$$

We denote the restricted maximum likelihood estimates of the variance components by $\hat{\sigma}_g^2$ and $\hat{\sigma}_e^2$.

For each of the 80 expression traits, we calculated fitted values for each subject with the estimated founder allele and covariate effects (Equation 3.11). We then calculated correlations between fitted values for pairs of traits. Each pairing involved one anchor gene expression trait and one other gene expression trait.

We anticipated that more similar two traits' founder allele effects would correspond, on average, to smaller pleiotropy test statistics. We base this expectation on findings from Macdonald and Long (2007) and King et al. (2012). Macdonald and Long (2007) and King et al. (2012) found that two traits that associate with a single pleiotropic QTL tended to have similar founder allele effects patterns for biallelic markers.

We performed two-dimensional QTL scans for $4*76+\binom{4}{2}=310$ pairs. Each pair included one of the four anchor gene expression traits and either one of 76 non-anchor gene expression traits or one of the remaining three anchor gene expression traits.

Our two-dimensional QTL scan encompassed a 1000 by 1000 marker grid from 18.1 Mb to 42.5 Mb on Chromosome 19. Each scan involved fitting $1000 \times 1000 = 1,000,000$ models via generalized least squares. For a given ordered pair of markers, we used the bivariate linear mixed effects model and methods defined in Chapter 2. These methods are implemented in the R package qtl2pleio (Boehm, 2018b).

For each of the 80 expression traits, we used the fitted founder allele and covariate effects $(\widehat{B}:\widehat{C})$ in Equation 3.11) to obtain fitted values vectors for every subject and all 80 traits (Equation 3.13). For each of the 310 pairings of traits, we calculated correlations among the fitted values vectors. Our motivation for working with the fitted values vectors (instead of the \widehat{B} estimated founder allele effects vectors) is that the fitted values approximately weight the allele effects by allele frequency. An alternative analysis might neglect the covariates when calculating fitted values.

$$\hat{Y} = X\hat{B} + W\hat{C} \tag{3.13}$$

3.2.3 Results

All four anchor traits demonstrate strong PWK ("G") allele effects. *Lipo2* and *Asah2* have similar patterns among allele effects (at their respective QTL peaks) (Table 3.4).

Each anchor gene has its own panel in Figure 3.7. Along the horizontal axis is Chromosome 19 position. The vertical axis is for pleiotropy test statistics. Each point corresponds to a local gene expression trait (paired with the appropriate anchor gene expression trait). Point color corresponds to the local gene's univariate LOD score, with lighter shades of blue denoting greater values of univariate LOD score. Vertical black bar denotes the anchor gene's position on Chromosome 19. All four panels reveal that points further from the anchor gene tend to show greater test statistic values. Additionally, because of their nearly identical positions, the Lipo1 and Lipo2 panels offer an opportunity to compare the impact of anchor gene univariate LOD score on pleiotropy test statistics. The difference in univariate LOD scores is modest, 85.5 for Lipo1 vs. 77.2 for Lipo2. The effect of univariate LOD scores is most apparent when examining local expression traits that have strong univariate LOD scores. For example, near 32 Mb is a point with light blue color. The light blue indicates that it has a high univariate LOD score. Lipo2, which has the lower univariate LOD score, shows a pleiotropy test statistic just over 30 when paired with this local expression trait. Lipo1 demonstrates a greater test statistic value, about 40, when paired with the same local expression trait.

Similarly, a local expression trait near 29 Mb has a strong univariate LOD score (near 100). We see that its pleiotropy test statistic values in the *Lipo1* and *Lipo2* panels reflect the difference in univariate LOD for

Figure 3.7: Each anchor gene has its own panel. Along the horizontal axis is Chromosome 19 position. The vertical axis is for pleiotropy test statistic value. Each point corresponds to a local gene expression trait (paired with the anchor gene). Point color corresponds to the local gene's univariate LOD score, with lighter shades of blue denoting greater values of univariate LOD score. Vertical black bar denotes the anchor gene's position on Chromosome 19. All four panels reveal that points further from the anchor gene tend to show greater test statistic values. Additionally, the Lipo1 and Lipo2 panels offer an opportunity to compare the impact of anchor gene univariate LOD score on pleiotropy test statistic values.

the two anchor gene expression traits. The pleiotropy test statistic value is greater when paired with Lipo1, the anchor gene expression trait with greater univariate LOD (compared to Lipo2).

In comparing the plot for Asah2 with those of Lipo1, Lipo2, and 4933413C19Rik, we also see that Asah2, with the largest (101.2) of the four univariate LOD scores, demonstrates the steepest ascent of points as interlocus distance increases.

Analyses for all four anchor gene expression traits demonstrate that greater univariate LOD scores tend to correspond to greater values of the pleiotropy test statistic (Figure 3.8). The coloring of points reflects interlocus distance from the anchor gene. All four panels reveal a common pattern in the coloring of points. For a given univariate LOD value, those genes with greater interlocus distance tend to have greater values

Figure 3.8: Vertical axis denotes pleiotropy test statistic value, while horizontal axis denotes univariate LOD score. Each point corresponds to a single gene expression trait. Panels correspond to the anchor gene expression trait. The pleiotropy test statistics correspond to analyses involving a single gene expression trait and the specified anchor gene expression trait.

of the pleiotropy test statistic. Anchor gene 4933413C19Rik, due to its position on Chromosome 19, has multiple light blue points. Nearly all of these light blue points have large pleiotropy test statistics relative to their univariate LOD scores.

Figure 3.9 features four panels, one for each anchor gene. Each point corresponds to a pairing between the specified anchor and one of the 79 other gene expression traits. None of the four panels reveals a strong relationship between fitted values correlation and pleiotropy test statistics. There may be weak evidence for a downward trend in pleiotropy test statistics at larger values of fitted values correlation, as demonstrated by Asah2, Lipo1, and Lipo2.

3.2.4 Discussion

Our goal for this study was to characterize the impacts of univariate LOD score, inter-locus distance, and founder allele effects pattern similarities on pleiotropy test statistic values. Our study design, in which we examined 310 pairs of local gene expression traits on Chromosome 19, allowed us to interrogate both the effects of univariate association strength and the effects of inter-locus distance. We found that stronger univariate associations and greater inter-locus distances correspond to greater pleiotropy test statistic values (Figures 3.7 and 3.8). We expected these trends based on our simulation studies in Chapter 2.

Figure 3.9 revealed no strong relationship between fitted values correlations and pleiotropy test statistics. However, close examination of Figure 3.9 reveals the possibility that there is an interaction between 1) fitted values correlations and 2) univariate LOD scores. In every panel, those expression traits with stronger univariate associations tend to have steeper slopes between the conditional mean pleiotropy test statistic values and fitted values correlations. The plots weakly suggest that, at greater univariate LOD values, there is a greater (negative) relationship between fitted values correlation and pleiotropy test statistic value.

We anticipated that more similar founder allele effects patterns would correspond to smaller values for the pleiotropy test statistic, when holding other factors constant. As we stated above, Macdonald and Long (2007) and King et al. (2012) argued that, for biallelic markers, two pleiotropic traits should have similar founder allele effects patterns. In our setting, it's unclear whether the markers are biallelic in the collection of eight founder lines.

We've demonstrated strong evidence in support of the roles of 1) univariate QTL LOD scores and 2) interlocus distances impacting pleiotropy test statistic values. Greater univariate QTL scores and greater interlocus distance lead to greater pleiotropy test statistics. Future research may clarify the impoact of founder allele effects patterns on pleiotropy test statistics. The fact that all four anchor traits had strong

Figure 3.9: Vertical axis denotes the pleiotropy test statistic value, and horizontal axis indicates absolute value of the correlation between vectors of fitted values. Each point corresponds to a pairing between the specified anchor expression trait and one of the 79 other expression traits.

PWK effects (Table 3.4) limited our ability to fully define the impact of allele effects patterns on our test statistics.

Throughout this study, we elected to use test statistic values rather than p-values as our measure of evidence supporting the separate QTL hypothesis. The primary reason for doing this is to avoid the computationally costly bootstrap sampling and two-dimensional QTL scans that we would need to get bootstrap p-values.

We share our analysis R code (R Core Team, 2018) as a git repository at this URL: https://github.com/fboehm/keller-2018-chr19-power.

3.3 Microbiome case study

3.3.1 Introduction

Recent technological innovations have fueled exploration of ecological relationships between gut microbiota and their hosts. Advances in mass spectrometry experimental methods have enabled high-throughput quantification of lipid levels and protein concentrations. These developments, when coupled with experiments to quantify the gut microbiome, have the potential to uncover new microbiome-host interactions. Such discoveries would lead to a more nuanced understanding of organismal biology and health implications of the gut microbiome.

Previous research demonstrated that hosts and gut microbiome communicate with each other via small molecule metabolites, including bile acids. The liver uses cholesterol to synthesize an array of bile acids. These bile acids are secreted into the gut, where members of the microbiome chemically transform some bile acids. One function of bile acids is to aid digestion by emulsification of dietary fats. While some bile acids are lost in the feces, much of the secreted bile acids is reabsorbed in the distal gut. Finally, reabsorbed bile acids are transported via the circulatory system back to the liver.

Below, we use our pleiotropy test to identify a pleiotropic QTL that affects both the abundance level of a group of bacteria in the distal gut and plasma cholic acid levels in the host. While many questions remain after our investigation, our identification of a single pleiotropic locus that affects these two phenotypes is an important preliminary step for further investigations.

Figure 3.10: Cholic acid chemical structure. From Wikipedia, https://upload.wikimedia.org/wikipedia/commons/2/21/Chols%C3%A4ure.svg.

3.3.2 Methods

As we describe in Kemis et al. (in preparation), we analyzed data from 384 Diversity Outbred mice. Keller et al. (2018) analyzed data from many of these same mice. Specifically, we examined two microbiome-related phenotypes, 1. plasma cholic acid and 2. *Turicibacter* abundance in the distal gut. Both traits map to Chromosome 8 (4.3 Mb and 5.7 Mb, respectively) in univariate QTL scans (Table 3.5).

Following the procedures in Kemis et al. (in preparation), we collected fecal samples from all mice immediately after a four-hour fast. We sacrificed the mice, at the age of 22 weeks, immediately after the fast. We extracted DNA from fecal samples and subjected it to 16S ribosomal RNA gene sequencing to infer abundances of microbial taxa. Demultiplexed, paired-end FASTQ files resulted from the sequencing. We used the QIIME2 (version 2018.4) software package (Bolyen et al., 2018) for quality control and processing of sequence data. We applied the DADA2 software package (Callahan et al., 2016) to denoise sequencing reads and to identify de novo sub-operational taxonomic units. We aligned sequence variants with the software package mafft (Katoh and Standley, 2013). After FastTree-based phylogeny reconstruction (Price, Dehal, and Arkin, 2010), we assigned taxonomic classifications with classify-sklearn against the Greengenes OTUs reference sequences (DeSantis et al., 2006). We normalized sequencing data with cumulative sum scaling with MetagenomeSeq (Paulson, Pop, and Bravo, 2013). We limited study of microbiome-derived traits to those that we detected in at least 20% of subjects. The *Turicibacter* abundance trait is one element of the resulting core measurable microbiota.

We collected plasma from each mouse at time of sacrifice. After removing soluble proteins, we analyzed

each mouse's sample by mass spectrometry to measure abundances of pre-specified bile acids. We processed and normalized plasma bile acid measurements to obtain phenotypes for QTL analysis.

We inferred 36-state genotype probabilities for every (autosomal) marker and every mouse from GigaMUGA SNP microarray data (Morgan et al., 2015). We used a hidden Markov model strategy developed by Karl W Broman (2012a) and Karl W Broman (2012b) and implemented in the R package qt12 (K. W. Broman et al., 2019). We treated these inferred genotype probabilities as known quantities in the analyses below. We calculated founder allele dosages by summing the appropriate genotype probabilities.

We then performed univariate QTL analyses for microbiome-related traits. For each marker and each univariate phenotype we fitted a linear mixed effects model (with a polygenic random effect), as implemented in the R package qt12 (K. W. Broman et al., 2019). We treated founder allele effects as additive and neglected possible interactions. We incorporated four covariates into the model: sex and three binary indicators for wave number.

We then calculated LOD values comparing the univariate models' log-likelihoods at each marker to the log-likelihood of the model without founder allele dosages, *i.e.*, the model with a single column of 1's replacing the eight columns of founder allele dosages. In summarizing LOD peak results, we identified a small region on Chromosome 8 that contains LOD peaks for both *Turicibacter* abundance and plasma cholic acid levels.

We estimated founder allele effects at Chromosome 8 markers using the univariate linear mixed effects model.

We then performed a test of pleiotropy vs. separate QTL for our two traits, *Turicibacter* abundance and plasma cholic acid levels, with the methods of Chapter 2. To calibrate our test statistic, we performed a parametric bootstrap analysis to acquire 1000 bootstrap samples.

With the collection of 1000 bootstrap test statistic values, we calculated a bootstrap p-value as the proportion of the 1000 tests, denoted by Λ_i , with i ranging from 1 to 1000, that were at least as extreme as the true test statistic Λ (Equation 3.14).

bootstrap p-value =
$$\frac{\#(\Lambda_i \ge \Lambda)}{1000}$$
 (3.14)

3.3.3 Results

The scatter plot of plasma cholic acid levels and Turicibacter abundance levels demonstrates modest correlation between the two traits (Pearson correlation coefficient = 0.5) (Figure 3.11). 192 of 384 mice have the smallest Turicibacter abundance level. Turicibacter was unobserved in fecal samples from these mice.

Figure 3.11: Scatter plot of plasma cholic acid levels against Turicibacter abundance

Plasma cholic acid founder allele effects

(a) Plasma cholic acid founder allele effects over the scan interval.

Turicibacter abundance founder allele effects

(b) Turicibacter abundance founder allele effects over the scan interval.

phenotype	chromosome	position	LOD
plasma cholic acid	1	91.61	5.37
Turicibacter abundance	2	17.20	5.40
plasma cholic acid	3	40.53	5.80
plasma cholic acid	7	122.19	6.83
plasma cholic acid	8	4.32	6.52
Turicibacter abundance	8	5.68	7.22
plasma cholic acid	12	16.60	5.24
Turicibacter abundance	12	76.34	5.17

Table 3.5: Genome-wide LOD peaks greater than 5 for plasma cholic acid levels and *Turicibacter* abundance. Both traits map to approximately the same region on Chromosome 8. Chromosome positions are in Mb units.

Univariate LOD plots for the two traits reveal broad LOD peaks on Chromosome 8 (Figure 3.12b). Plasma cholic acid's peak starts about 4 Mb and extends to approximately 6.5 Mb. *Turicibacter* abundance has an even broader peak, starting about 4 Mb and extending to 7.5 Mb. Although the two traits' peak position point estimates differ by 1.4 Mb, the univariate LOD plots demonstrate highly similar patterns for the two traits.

It is unclear from the univariate LOD plots whether there are two nearby QTLs that both affect *Turicibacter* abundance (Figure 3.12b). Consistent with the possibility of two peaks is the observation that the *Turicibacter* peak extends further to the right than does the plasma cholic acid peak.

Founder allele effects plots for the two traits demonstrate similarities in the relative magnitudes of the eight effects. Specifically, the plasma cholic acid founder allele effects, at 5Mb, has AJ, NZO, CAST, and 129 above average, while WSB is well below average. Similarly, *Turicibacter* abundance has founder allele effects at 5Mb with AJ and 129 above average and WSB below average.

The profile LOD plot over our two-dimensional scan region reveals broad for both traits' profile LODs (Figure 3.13). Plasma cholic acid has a peak that begins about 4 Mb and extends to approximately 6.5 Mb. *Turicibacter* abundance has a broader peak, with endpoints near 4 Mb and 7.5 Mb. Here, but not in the univariate LOD plots, one sees a second peak in the *Turicibacter* abundance phenotype that begins near 7.5 Mb and ends near 8.7 Mb.

We used the R package qtl2pleio (Boehm, 2018b) to calculate the likelihood ratio test statistic, $\Lambda = 0.45$. We determined the bootstrap p-value to be 0.531 with 1000 bootstrap samples. Thus, we failed to reject the null hypothesis of pleiotropy.

Figure 3.13: Profile LODs for Turicibacter abundance and plasma cholic acid levels.

3.3.4 Discussion

We've illustrated another scientific application of our pleiotropy test. We plan to perform additional statistical analyses, including mediation studies, with these data. Our pleiotropy test tells us that the data are consistent with presence of a single QTL affecting both *Turicibacter* abundance and plasma cholic acid levels, but it doesn't provide information about the possibilities that plasma cholic acid levels affect *Turicibacter* abundance or that *Turicibacter* abundance affects plasma cholic acid levels. Both of these possibilities are biologically plausible. Future mediation analyses may clarify these issues.

Chapter 4

Computing vignettes

4.1 Pleiotropy testing vignette

4.1.1 Setting for pleiotropy vs. two separate QTL

Our setting involves a pair of traits, Y_1 and Y_2 , each of which individually (univariately) maps to a single genomic region. Y_1 and Y_2 are both measured on the same subjects. The exact definition of a genomic region is imprecise; in practice, it may be as large as 4 or 5 Mb. We seek to distinguish whether Y_1 and Y_2 associations (in the genomic region of interest) arise due to a single QTL or whether there are two two distinct loci, each of which associates with exactly one of the two traits. We recognize that more complicated association patterns are possible, but we neglect them in this test.

4.1.2 Installing qtl2pleio

We install qtl2pleio from github via the devtools R package, which is available from CRAN.

If you haven't installed devtools R package, you can do so with this line of code:

install.packages("devtools")

Now that you have installed devtools, you can install qtl2pleio from its Github repository with this line of code:

```
devtools::install_github("fboehm/qtl2pleio")
```

The above line only needs to be run once on a given computer (unless you wish to install a newer version of the package).

We then load the library into our R session with the library command:

```
library(qtl2pleio)
```

We'll work with data from the qt12data repository, which is on github. First, we install and load the qt12 package.

```
devtools::install_github("rqtl/qtl2")
```

We use the above line once to install the package on our computer before loading the package with the library command.

```
library(qtl2)
```

4.1.3 Reading data from qtl2data repository on github

We read from github.com data from the qtl2data repository.

```
pm2 <- pmap_pre[pmap_pre$chr == 2, 3]
names(pm2) <- pmap_pre[pmap_pre$chr == 2, 1]
pm3 <- pmap_pre[pmap_pre$chr == 3, 3]
names(pm3) <- pmap_pre[pmap_pre$chr == 3, 1]
pmX <- pmap_pre[pmap_pre$chr == "X", 3]
names(pmX) <- pmap_pre[pmap_pre$chr == "X", 1]
list(pm2, pm3, pmX) -> pm
names(pm) <- c("`2`", "`3`", "X")</pre>
```

We now have an allele probabilities object stored in pr.

```
names(pr)

#> [1] "2" "3" "X"

dim(pr$^2^)

#> [1] 261 8 127
```

We see that pr is a list of 3 three-dimensional arrays - one array for each of 3 chromosomes.

4.1.4 Kinship calculations

For our statistical model, we need a kinship matrix. Although we don't have genome-wide data - since we have allele probabilities for only 3 chromosomes - let's calculate a kinship matrix using "leave-one-chromosome-out". In practice, one would want to use allele probabilities from a full genome-wide set of markers.

```
calc_kinship(probs = pr, type = "loco") -> kinship
```

```
str(kinship)
#> List of 3
#> $ 2: num [1:261, 1:261] 0.6919 0.0707 0.2355 0.0558 0.0512 ...
#> ..- attr(*, "n_pos")= int 195
#> ..- attr(*, "dimnames")=List of 2
#> ...$: chr [1:261] "1" "4" "5" "6" ...
#> ...$: chr [1:261] "1" "4" "5" "6" ...
```

```
#> $ 3: num [1:261, 1:261] 0.6642 0.0638 0.2035 0.1128 0.0772 ...

#> ..- attr(*, "n_pos") = int 220

#> ... attr(*, "dimnames") = List of 2

#> ... $: chr [1:261] "1" "4" "5" "6" ...

#> ... $: chr [1:261] "1" "4" "5" "6" ...

#> $ X: num [1:261, 1:261] 0.4853 0.0821 0.1958 0.1039 0.1123 ...

#> ..- attr(*, "n_pos") = int 229

```

We see that kinship is a list containing 3 matrices. Each matrix is 261 by 261 - where the number of subjects is 261 - and symmetric. The (i, j) cell in the matrix contains the estimate of identity-by-state (IBS) probability for randomly chosen alleles at a single locus for those two subjects.

Before we simulate phenotype data, we first specify our statistical model.

We use the model:

$$vec(Y) = Xvec(B) + vec(G) + vec(E)$$

where Y is a n by 2 matrix, where each row is one subject and each column is one quantitative trait. X is a 2n by 2f design matrix containing n by f allele probabilities matrices for each of two (possibly identical) markers. Thus, X is a block-diagonal matrix, with exactly two n by f blocks on the diagonal. B is a f by 2 matrix. "vec" refers to the vectorization operator. "vec(B)", where B is a f by 2 matrix, is, thus, a (column) vector of length 2f that is formed by stacking the second column of B beneath the first column of B.

G is a matrix of random effects. We specify its distribution as matrix-variate normal with mean being a n by 2 matrix of zeros, covariance among row vectors a n by n kinship matrix, K, and covariance among column vectors a 2 by 2 genetic covariance matrix, V_a .

In mathematical notation, we write:

$$G \sim MN_{\text{n by 2}}(0, K, V_q)$$

We also need to specify the distribution of the E matrix, which contains the random errors. E is a random

n by 2 matrix that is distributed as a matrix-variate normal distribution with mean being the n by 2 zero matrix, covariance among row vectors I_n , the n by n identity matrix, and covariance among columns the 2 by 2 matrix V_e .

$$E \sim MN_{\text{n by 2}}(0, I_n, V_e)$$

In practice, we typically observe the phenotype matrix Y. We also treat as known the design matrix X and the kinship matrix K. We then infer the values of B, V_q , and V_e .

4.1.5 Simulating phenotypes with qtl2pleio::sim1

The function to simulate phenotypes in qtl2pleio is sim1. By examining its help page, we see that it takes five arguments. The help page also gives the dimensions of the inputs.

```
# set up the design matrix, X
pp <- pr[[2]]
X <- gemma2::stagger_mats(pp[ , , 50], pp[ , , 50])</pre>
# assemble B matrix of allele effects
# verify that B is what we want:
#>
      [,1] [,2]
#> [1,] -1 -1
#> [2,] -1
#> [3,] -1
#> [4,] -1
#> [5,]
      1
          1
#> [6,]
#> [7,]
       1
            1
#> [8,]
        1
# set.seed to ensure reproducibility
set.seed(2018-01-30)
# call to sim1
```

```
Ypre <- sim1(X = X, B = B, Vg = diag(2), Ve = diag(2), kinship = kinship[[2]])
Y <- matrix(Ypre, nrow = 261, ncol = 2, byrow = FALSE)
rownames(Y) <- rownames(pp)
colnames(Y) <- c("tr1", "tr2")</pre>
```

Let's perform univariate QTL mapping for each of the two traits in the Y matrix.

```
scan1(genoprobs = pr, pheno = Y, kinship = kinship) -> s1
```

```
find_peaks(s1, map = pm)
     lodindex lodcolumn chr
                                  pos
                                            lod
#> 1
            1
                    tr1 `2` 75.562440 3.636498
#> 2
                    tr1 `3` 82.778059 24.552172
#> 3
            1
                    tr1
                          X 13.406552 3.585519
#> 4
                    tr2 `2` 3.164247 8.195879
            2
#> 5
            2
                    tr2 `3` 82.778059 17.454825
                        X 95.069663 14.110670
#> 6
                    tr2
```

4.1.6 Perform two-dimensional scan as first step in pleiotropy v separate QTL hypothesis test

Create a profile LOD plot to visualize results of two-dimensional scan

```
library(dplyr)
out %>%

tidy_scan_pvl(pm3) %>% # pm3 is physical map for Chr 3

add_intercepts(intercepts_univariate = c(82.8, 82.8)) %>%

plot_pvl(phenames = c("tr1", "tr2"))

#> Warning: Removed 50 rows containing missing values (geom_path).
```

Calculate the likelihood ratio test statistic for pleiotropy v separate QTL

We use the function calc_lrt_tib to calculate the likelihood ratio test statistic value for the specified traits and specified genomic region.

```
(calc_lrt_tib(out) -> lrt)
#> [1] 0.7730965
```

4.1.7 Bootstrap analysis to get p-values

The calibration of test statistic values to get p-values uses bootstrap methods because we don't know the theoretical distribution of the test statistic under the null hypothesis. Thus, we use a bootstrap approach to obtain an empirical distribution of test statistic values under the null hypothesis of the presence of one pleiotropic locus.

We will use the function boot_pvl from our package qtl2pleio.

We use a parametric bootstrap strategy in which we first use the studied phenotypes to infer the values of model parameters. Once we have the inferred values of the model parameters, we simulate phenotypes from the pleiotropy model (with the inferred parameter values).

A natural question that arises is "which marker's allele probabilities do we use when simulating phenotypes?" We use the marker that, under the null hypothesis, ie, under the pleiotropy constraint, yields the greatest value of the log-likelihood.

Before we call boot_pvl, we need to identify the index (on the chromosome under study) of the marker that maximizes the likelihood under the pleiotropy constraint. To do this, we use the qtl2pleio function find_pleio_peak_tib.

```
(pleio_index <- find_pleio_peak_tib(out, start_snp = 38))
#> loglik13
#> 50
```

```
set.seed(2018-10-03)
system.time(b_out <- boot_pvl(probs = pp,</pre>
         pheno = Y,
         pleio_peak_index = pleio_index,
         kinship = kinship[[2]], # 2nd element in kinship list is Chr 3
         nboot_per_job = 10,
         start_snp = 38,
         n_{snp} = 10
         ))
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
```

```
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation with data from 261 subjects.
#> covariance matrices estimation completed.
#> starting covariance matrices estimation completed.
```

The argument nboot_per_job indicates the number of bootstrap samples that will be created and analyzed. Here, we set nboot_per_job = 10, so we expect to see returned a numeric vector of length 10, where each entry is a LRT statistic value from a distinct bootstrap sample.

Finally, we determine a bootstrap p-value in the usual method. We treat the bootstrap samples' test statistics as an empirical distribution of the test statistic under the null hypothesis of pleiotropy. Thus, to get a p-value, we want to ask "What is the probability, under the null hypothesis, of observing a test statistic value that is at least as extreme as that which we observed?"

```
(pvalue <- mean(b_out >= lrt))
#> [1] 0.1
```

Typically, one would want to conduct the two-dimensional scan over a larger grid (ie, with more markers). We abbreviated the scan above to reduce computing time.

In practice, one would want to use many more bootstrap samples to achieve an empirical distribution that is closer to the theoretical distribution of the test statistic under the null hypothesis.

However, if one wants to perform analyses with a reasonable number - say 400 - bootstrap samples, this will take a very long time - several days - on a single laptop computer. We have used a series of computer clusters that are coordinated by the University of Wisconsin-Madison's Center for High-throughput

Computing (http://chtc.cs.wisc.edu). We typically are able to analyze 1000 bootstrap samples in less than 24 hours with this service.

We recently added parallel computing capacity with boot_pvl and scan_pvl. The user may specify n_cores when calling each function.

4.2 Recla data analysis vignette

4.2.1 Load Recla from qtl2data github repository

```
probs <- calc_genoprob(recla, map = pseudomap)</pre>
```

We now convert the genotype probabilities to haplotype dosages.

```
aprobs <- genoprob_to_alleleprob(probs)
```

We now calculate kinship matrices, by the "leave one chromosome out (loco)" method.

```
kinship <- calc_kinship(aprobs, "loco")</pre>
```

```
recla$pheno -> ph
log(ph) -> lph
apply(FUN = broman::winsorize, X = lph, MARGIN = 2) -> wlph
#colnames(wlph)[c(7, 10, 22)] <- c("distance traveled in light", "percent time in light", "hot plate la
as_tibble(wlph) -> wlph_tib
```

We next perform the univariate QTL scan for our phenotypes.

```
sex2 <- matrix(as.numeric(sex == "female"), ncol = 1)

colnames(sex2) <- "female"

rownames(sex2) <- rownames(aprobs[[1]])

out <- scan1(genoprobs = aprobs, pheno = wlph, kinship = kinship, addcovar = sex2, reml = TRUE)</pre>
```

Let's find the univariate QTL peaks for all phenotypes.

We want to look closely at those peaks on Chromosome 8. We'll save the positions of peaks for our two traits of interest.

```
(peaks <- find_peaks(out, pseudomap, threshold = 5) %>%
arrange(chr, pos) %>%
select(- lodindex))
```

```

## 71
## 72
             VC_top_time_first4 18 17.8068 6.246206
```

```
## 73 LD_transitions 18 37.4182 5.090332

## 74 VC_bottom_distance_first4 19 24.9615 7.362557

## 75 VC_bottom_time_first4 19 24.9615 7.499959

## 76 OF_immobile_pct 19 31.9505 5.639812

## 77 HP_latency 19 47.7977 5.485000
```

```
peaks8 <- peaks %>%
  filter(chr == 8, pos > 50, pos < 60)

pos_LD_light_pct <- peaks8 %>%
  filter(lodcolumn == "LD_light_pct") %>%
  select(pos)

pos_HP_latency <- peaks8 %>%
  filter(lodcolumn == "HP_latency") %>%
  select(pos)
```

4.2.2 Correlation

Given that the two traits "percent time in light" and "distance traveled in light" share a peak, we want to ask how correlated they are.

```
cor(wlph[ , 7], wlph[ , 10], use = "complete.obs")

## [1] 0.8859402

cor(wlph[ , 22], wlph[ , 10], use = "complete.obs")

## [1] -0.1507317

cor(wlph[ , 7], wlph[ , 22], use = "complete.obs")

## [1] -0.143598
```

Since "percent time in light" and "distance traveled in light" are very highly correlated, we'll discard "distance traveled in light" and perform subsequent analyses with only "percent time in light" and the second trait, "hot plate latency".

4.2.3 Scatter plot of phenotypes

We create a scatter plot for the two phenotypes, "hot plate latency" and "percent time in light".

```
scatter1022 <- ggplot() + geom_point(data = wlph_tib, aes(y = HP_latency, x = LD_light_pct)) + labs(x =
scatter1022</pre>
```

Warning: Removed 3 rows containing missing values (geom_point).

Scatterplot of hot plate latency vs. percent time in light

4.2.4 Genome-wide LOD plots for the traits from Recla

Let's plot the results of the univariate QTL scans for our two traits.

```
plot(out, map = pseudomap, lodcolumn = 10, main = "Genome-wide LOD for percent time in light")
```

Genome-wide LOD for percent time in light

plot(out, map = pseudomap, lodcolumn = 22, main = "Genome-wide LOD for hot plate latency")

Genome-wide LOD for hot plate latency

4.2.5 Allele effects plots on Chr 8 for each of the three Recla traits

We examine the allele effects plots for our two traits, in the region of interest on Chromosome 8.

```
# subset scan1output objects s1c\_10s \leftarrow s1c\_10[650:999, ] \text{ # } 650:999 \text{ is the same as the interval for the two-dimensional scan.} \\ s1c\_22s \leftarrow s1c\_22[650:999, ]
```

```
plot_coefCC(s1c_10s, map = pseudomap, main = "Allele effects for percent time in light")
```

Allele effects for percent time in light

plot_coefCC(s1c_22s, map = pseudomap, main = "Allele effects for hot plate latency")

Allele effects for hot plate latency

4.2.6 Two-dimensional scan results from github

We present the code that we ran to perform the two-dimensional scan.

```
scan_pvl(probs = pp, pheno = wlph[, c(10, 22)], covariates = sex2, kinship = kinship$^8^, start_snp1 =
write.table(x = pvl1022, file = "recla-10-22.txt")
```

To save computing time, we read the two-dimensional scan results from Github.

```
as_tibble(read.table("https://raw.githubusercontent.com/fboehm/qtl2pleio-manuscript/master/Rmd/recla-10
```

We then calculate the likelihood ratio test statistic.

```
(mylrt <- calc_lrt_tib(pv11022))</pre>
```

[1] 2.771408

4.2.7 Profile LOD Plot

We create a profile LOD plot.

```
colnames(recla$pheno)[c(10, 22)] <- c("Percent time in light", "Hot plate latency")
p1022 <- tidy_scan_pvl(pvl1022, pmap = gm) %>%
    add_intercepts(c(as.numeric(pos_LD_light_pct), as.numeric(pos_HP_latency))) %>%
    plot_pvl(phenames = colnames(recla$pheno)[c(10, 22)]) + ggtitle("Chromosome 8 profile LOD for percent")
## Warning: Column `marker'/`marker1` joining character vector and factor,
## coercing into character vector
## Warning: Column `marker2'/`marker` joining factor and character vector,
```

4.2.8 Bootstrap analyses

coercing into character vector

First, we find the *pleiotropy peak* marker. This is the marker for which the log likelihood is maximized under the constraint of pleiotropy.

```
find_pleio_peak_tib(pvl1022, start_snp = 650)

## loglik139
## 788
```

To save computing time, we read the bootstrap results files from Github. For details of how we performed the bootstrap analyses on the University of Wisconsin-Madison Center for High-Throughput Computing, please see the documentation in the qtl2pleio-manuscript repository: https://github.com/fboehm/qtl2pleio-manuscript.

The code below creates a temporary directory "tmp" in the user's working directory. We then download a gzipped tar file that contains 1000 text files. Each text file contains a single likelihood ratio test statistic from a bootstrap sample.

```
gz_file <- "https://raw.githubusercontent.com/fboehm/qtl2pleio-manuscript/master/chtc/Recla-bootstrap/s</pre>
tmp_dir <- file.path(getwd(), "tmp")</pre>
dir.create(tmp_dir)
download.file(gz_file, destfile = file.path(tmp_dir, "recla-boot-run561.tar.gz"))
untar(file.path(tmp_dir, "recla-boot-run561.tar.gz"), exdir = tmp_dir)
## read boot lrt files
boot_lrt <- list()</pre>
for (i in 1:1000){
  n <- i - 1
  fn <- paste0("recla-boot-run561_", n, ".txt")</pre>
  boot_lrt[i] <- read.table(file.path(tmp_dir, fn))</pre>
}
# convert list to numeric vector
boot_lrt <- unlist(boot_lrt)</pre>
\# delete tmp\_dir and its contents
unlink(tmp_dir, recursive = TRUE)
```

We get a bootstrap p-value by comparing the above vector's values to mylrt, the test statistic for the observed data.

```
sum(boot_lrt >= mylrt) / length(boot_lrt)
## [1] 0.109
```

4.2.9 Session info

```
devtools::session_info()

Appendix A

Supplementary materials for Chapter

2

Table ${f S1}$: Eight founder lines and their one-letter abbreviations.

Founder allele	One-letter abbreviation
A/J	A
C57BL/6J	В
129S1/SvImJ	C
NOD/ShiLtJ	D
NZO/H1LTJ	E
Cast/EiJ	F
PWK/PhJ	G
WSB/EiJ	Н

Table S2: Both "hot plate latency" and "percent time in light" demonstrate multiple QTL peaks with LOD scores above 5.

phenotype	chr	pos	LOD score
percent time in light	8	55.28	5.27
hot plate latency	8	57.77	6.22
percent time in light	9	36.70	5.42
hot plate latency	9	46.85	5.22
percent time in light	11	63.39	6.46
hot plate latency	12	43.52	5.13
percent time in light	15	15.24	5.67
hot plate latency	19	47.80	5.48

hot plate latency vs. percent time in light 3.0 2.5 1.5 1.0 1.10 1

Figure S1: Scatter plot of "hot plate latency" against "percent time in light", after applying logarithm transformations and winsorizing both traits.

percent time in light

hot plate latency

Figure S2: Genome-wide QTL scan for percent time in light reveals multiple QTL, including one on Chromosome 8.

Appendix B

Supplementary materials for Chapter

3

Table S1: LOD peak positions and peak heights for 147 expression traits that map to the Chromosome 2 expression trait hotspot. We see that some transcript levels have LOD scores below the 7.18 genome-wide threshold. We believe that this is due to variations in statistical modeling between our analyses and those of Keller et al. (2018).

Gene	Peak position	LOD
Mtfp1	163.52	17.79
Slc12a7	163.58	8.30
Gpa33	163.58	26.38
Tmem25	163.58	11.26
